

## Description

Three- or four-pole low-voltage power switch with Rogowski coils operating as current sensors

The invention relates to a three-pole or four-pole low-voltage power switch using Rogowski coils as current sensors, an electronic overcurrent release and a device for ground-fault detection, the outputs of the Rogowski coils each being taken via an RC low-pass filter to an instrumentation amplifier of the overcurrent release.

Three-pole or four-pole low-voltage power switches are sometimes fitted with a device for ground-fault detection. To detect a ground fault, it is necessary to form the vectorial sum of the currents in the three/four conductors of the monitored electrical power network. It is also possible to connect an external summation current transformer, which summates the primary currents directly. Depending on the requirements of the switching installation in which the power switch is used, a detected ground fault is either merely signaled or causes the switch to trip after a preset delay.

If the power switch works using Rogowski coils as current sensors, as disclosed in German patent DE 100 54 496 A1 for example, the currents in the Rogowski coils are far too small for a summation evaluation according to the type of detection in the neutral conductor described in the introduction. In order to still be able to detect ground faults, the practice until now was to generate by calculation the summation current from the individual current signals, after their analog-to-digital conversion in the microprocessor, and to provide it as a digital value.

The sampling in the processor results in errors, because the processor detects the individual analog-to-digital converter values with a time offset from one phase to the next. This means that the signal is measured with a time difference of 90 µs from phase L1 to phase N. Although the summation current can be calculated by interpolation and backward projection to the first of three/four sample values in each case, a significant systematic error still remains, in particular when there are dynamic current variations in the power network.

The object of the invention is to enable ground-fault detection in a simpler manner for a low-voltage power switch of the type cited in the introduction using Rogowski coils as current sensors.

The object is achieved according to the invention by the features of claim 1.

According to claim 1, the output signals of all the Rogowski coils are taken via resistors in common to an integration capacitor, whose voltage forms the input signal of an additional instrumentation amplifier indicating the summation current in the monitored power network. The output signal of this instrumentation amplifier is then processed further in the microprocessor of the overcurrent release in a manner known in the art.

The invention shall be described in more detail below with reference to an exemplary embodiment. The associated drawing shows in a block diagram the current detection system for an electronic overcurrent release of a low-voltage power switch.

Rogowski coils 1 are used as sensors for detecting the currents in the power network. The outputs of the Rogowski coils 1 are taken via a symmetric low-pass RC circuit 2 to the inputs of instrumentation amplifiers 3. At their outputs lie the signals IL1, IL2, IL3, ILN proportional to the power-network currents for the three phase conductors and the neutral conductor of the power network, which are then taken via AD-converters (not shown here) to a microprocessor, which monitors the signals IL1, IL2, IL3, ILN for inadmissibly high values, and, if applicable, causes the power switch to trip immediately or after a delay.

In addition to detecting the individual currents, summation is now also provided on the analog side of the overcurrent release. For this purpose, the output signals of the Rogowski coils 1 are each taken via a symmetrical low-pass filter comprising the resistors 4 and 5 and a common integration capacitor 6 to an additional instrumentation amplifier 7, at whose output lies a signal ISumme, which represents the sum of all the currents in the monitored power network. If the summation current (minus a preset tolerance value) does not equal zero, then there is a ground fault in the area located after the power switch. The ground fault is signaled by a visual indicator, and, if applicable, also causes the overcurrent release to trip after a preset delay and hence to disconnect the connected loads.

Using the arrangement it is possible to select the measurement range of the current summation in terms of the gain so that the analog-to-digital converter is driven over its maximum range. The sampling error that previously occurred no longer exists.
